Abstract. Solar, atmospheric, and reactor neutrino experiments have confirmed neutrino oscillations, implying that neutrinos have non-zero mass, but without pinning down their absolute masses. While it is established that the effect of neutrinos on the evolution of cosmic structure is small, the upper limits derived from large-scale structure could help significantly to constrain the absolute scale of the neutrino masses. In a recent paper the 2dF Galaxy Redshift Survey (2dFGRS) team provided an upper limit $m_{\nu,\text{tot}} < 2.2$ eV, i.e. approximately 0.7 eV for each of the three neutrino flavours, or phrased in terms of their contribution to the matter density, $\Omega_\nu/\Omega_m < 0.16$. Here we discuss this analysis in greater detail, considering issues of assumed ‘priors’ like the matter density Ω_m and the bias of the galaxy distribution with respect to the dark matter distribution. As the suppression of the power spectrum depends on the ratio Ω_ν/Ω_m , we find that the out-of-fashion Mixed Dark Matter model, with $\Omega_\nu = 0.2$, $\Omega_m = 1$ and no cosmological constant, fits both the 2dFGRS power spectrum and the CMB data reasonably well, but only for a Hubble constant $H_0 < 50$ km s⁻¹ Mpc⁻¹. As a consequence, excluding low values of the Hubble constant, e.g. with the HST Key Project, is important in order to get a strong upper limit on the neutrino masses. We also comment on the improved limit obtained by the WMAP team, and point out that the main neutrino signature comes from the 2dFGRS and the Lyman α forest.

1. Introduction

The wealth of new data from e.g. the cosmic microwave background (CMB) and large-scale structure (LSS) in the last few years indicate that we live in a flat Universe where $\sim 70\%$ of the mass-energy density is in the form of dark energy, with matter making up the remaining 30% . The WMAP data combined with other large-scale structure data [1] gives impressive support to this picture. Furthermore, the baryons contribute only a fraction $f_b = \Omega_b/\Omega_m \sim 0.15$ (Ω_b and Ω_m are, respectively, the contribution of baryons and of all matter to the total density in units of the critical density $\rho_c = 3H_0^2/8\pi G = 1.879 \times 10^{-29} h^2 \text{ g cm}^{-3}$, where $H_0 = 100h \text{ km s}^{-1} \text{ Mpc}^{-1}$ is the present value of the Hubble parameter) of this, so that most of the matter is dark. The exact nature of the dark matter in the Universe is still unknown. Relic neutrinos are abundant in the Universe, and from the observations of oscillations of solar and atmospheric neutrinos we know that neutrinos have a mass [2, 3, 4, 5, 6, 7, 8] and will make up a fraction of the dark matter. However, the oscillation experiments can only measure differences in the squared masses of the neutrinos, and not the absolute mass scale, so they cannot tell us how much of the dark matter is in neutrinos. From general arguments on structure formation in the Universe we know that most of the dark matter has to be cold, i.e. non-relativistic when it decoupled from the thermal background. Neutrinos with masses on the eV scale or below will be a hot component of the dark matter. If they were the dominant dark-matter component, structure in the Universe would have formed first at large scales, and smaller structures would form by fragmentation (the ‘top-down’ scenario). However, the combined observational and theoretical knowledge about large-scale structure gives strong evidence for the ‘bottom-up’ picture of structure formation, i.e. structure formed first at small scales. Hence, neutrinos cannot make up all of the dark matter (see [9] for a review). Neutrino experiments give some constraints on how much of the dark matter can be in the form of neutrinos. Studies of the energy spectrum in tritium decay [10] provide an upper limit on the electron neutrino mass of 2.2 eV (95 % confidence limit). For the effective neutrino mass scale involved in neutrinoless double beta decay an upper limit of 0.34 eV (90 % confidence) has been inferred [11] but then under the assumptions that neutrinos are Majorana particles (i.e. their own antiparticles), and the translation from the effective neutrino mass scale in neutrinoless double beta decay to neutrino mass eigenvalues requires assumptions about the neutrino mass hierarchy and the CP phases in the neutrino mixing matrix.

From cosmology, an analysis the 2dF Galaxy Redshift Survey [12] found $m_{\nu,\text{tot}} < 2.2 \text{ eV}$ as an upper limit on the sum of the (degenerate) mass eigenvalues. In [13] the 2dFGRS was combined with pre-WMAP CMB data to give an upper limit $m_{\nu,\text{tot}} < 0.9 \text{ eV}$. The WMAP team [1] improved this result to $m_{\nu,\text{tot}} < 0.71 \text{ eV}$ (95 % confidence) from a combination of WMAP, ACBAR [14], CBI [15] for the CMB, and 2dFGRS and the power spectrum inferred from Lyman α forest [16, 17] for large scale structure, a factor of roughly three better than the 2dFGRS limit (not an order

of magnitude as stated in [1]). This limit is comparable to what the pioneering study in [19] predicted would be possible with the Sloan Digital Sky Survey [18] and WMAP [19], and have implications for neutrino oscillation experiments as it seems to call into question the Liquid Scintillator Neutrino Detector (LSND) result [20], where the mass-square difference involved was $\sim 1 \text{ eV}^2$ [21, 22]. (However, as pointed out in [23] it is premature to say that cosmology rules out the LSND results.) Note that neutrinos with eV masses are basically indistinguishable from cold dark matter at the epoch of last scattering, and therefore they have little effect on the CMB. The important role of the WMAP data in the cosmological neutrino mass limit is to break degeneracies in the parameter space that will otherwise limit the ability to constrain neutrino masses from the large-scale structure data.

In this paper we discuss in detail the recent cosmological neutrino mass limits, concentrating on the 2dFGRS and the WMAP + 2dFGRS limits and the various parameter degeneracies involved in the analysis. In particular we discuss the role of the bias of the galaxy distribution with respect to the mass distribution, non-linear effects, and the necessity of using independent information about cosmological parameters like Ω_m and h ('priors'). We will throughout this paper work within the context of flat Λ CDM models, which are favoured by a wealth of observational data [1, 24, 13], however we also comment on Mixed Dark Matter (MDM) models in discussion of the analysis of the 2dFGRS data. In fact we find that an MDM model can still provide a reasonable fit to the 2dFGRS and WMAP data, although with a low Hubble constant, so that external constraints on the Hubble constant are important in order to get a strong upper limit on the neutrino masses.

The structure of this paper is as follows: in section 2 we give a brief overview of how neutrinos affect structure formation in the Universe. In section 3 we consider galaxy redshift surveys as a probe of neutrino masses, starting with a brief summary of the analysis in [12]. Since the exact relationship between the distribution of the galaxies and that of the dark matter is unknown, we discuss different ways of taking this uncertainty into account. We also discuss the role of priors on parameters degenerate with massive neutrinos. In section 4 we give a brief overview of other cosmological probes of neutrino masses before we summarize and conclude in section 5.

2. Massive neutrinos and structure formation

The relic abundance of neutrinos in the Universe today is straightforwardly found from the fact that they continue to follow the Fermi-Dirac distribution after freeze-out, and their temperature is given in terms of the CMB temperature T_{CMB} today as $T_\nu = (4/11)^{1/3} T_{\text{CMB}}$,

$$n_\nu = \frac{6\zeta(3)}{11\pi^2} T_{\text{CMB}}^3, \quad (1)$$

where $\zeta(3) \approx 1.202$, which gives $n_\nu \approx 112 \text{ cm}^{-3}$ at present. Neutrinos are so light that they were ultra-relativistic at freeze-out. Their present contribution to the mass density

can therefore be found by multiplying n_ν with the total mass of the neutrinos $m_{\nu,\text{tot}}$, giving

$$\Omega_\nu h^2 = \frac{m_{\nu,\text{tot}}}{94 \text{ eV}}, \quad (2)$$

for $T_{\text{CMB}} = 2.728 \text{ K}$. Several effects could modify this simple relation. If any of the neutrino chemical potentials were initially non-zero, or there were a sizable neutrino-antineutrino asymmetry, this would increase the energy density in neutrinos and give an additional contribution to the radiation energy density. However, from Big Bang Nucleosynthesis (BBN) one gets a very tight limit on the electron neutrino chemical potential, since the electron neutrino is directly involved in the processes that set the neutron-to-proton ratio. Also, within the standard three-neutrino framework one can extend this limit to the other flavours as well. The recent results of the KamLAND experiment [25] confirmed the Large Mixing Angle (LMA) solution for the solar neutrino oscillations, and combined with the atmospheric data indicating maximal mixing in this sector, it has been shown that flavour equilibrium is established between all three neutrino species before the epoch of BBN [26, 27, 28], so that the BBN constraint on the electron neutrino asymmetry applies to all flavours, which in turn implies that the lepton asymmetry cannot be large enough to give a significant contribution to the radiation energy density. Recent analyses of WMAP and 2dFGRS data give independent, although not quite as strong, evidence for small lepton asymmetries [23, 29]. Within the standard picture, equation (1) should be accurate, and therefore any constraint on the cosmic mass density of neutrinos should translate straightforwardly into a constraint on the total neutrino mass, according to equation (2). If a fourth, light ‘sterile’ neutrino exists, sterile-active oscillations would modify this conclusion. No sterile neutrinos are required to explain the solar and atmospheric neutrino oscillation data [30], and the only hint so far comes from the possible detection of $\bar{\nu}_\mu \rightarrow \bar{\nu}_e$ oscillations with a small mixing angle and a mass-square difference $\sim 1 \text{ eV}^2$ at the LSND [20]. Since there are only two independent mass-squared differences in the standard three-neutrino scenario, and they are orders of magnitude smaller, this hints at the existence of a fourth, light sterile neutrino. However, as said, this has little support in the solar and atmospheric data. The status of the LSND results will in the near future be clarified by the MiniBooNE experiment [31].

Finally, we assume that the neutrinos are nearly degenerate in mass. Current cosmological observations are sensitive to neutrino masses $\sim 1 \text{ eV}$ or greater. Since the mass-square differences are small, the assumption of a degenerate mass hierarchy is therefore justified. This is illustrated in figure 1, where we have plotted the mass eigenvalues m_1, m_2, m_3 as functions of $m_{\nu,\text{tot}} = m_1 + m_2 + m_3$ for $\Delta m_{21}^2 = 5 \times 10^{-5} \text{ eV}^2$ (solar) and $\Delta m_{32}^2 = 3 \times 10^{-3} \text{ eV}^2$ (atmospheric), for the cases of a normal hierarchy ($m_1 < m_2 < m_3$), and an inverted hierarchy ($m_3 < m_1 < m_2$). As seen in the figure, for $m_{\nu,\text{tot}} > 0.4 \text{ eV}$ the mass eigenvalues are essentially degenerate.

We will in this paper look at cosmological models with four components: baryons, cold dark matter, massive neutrinos, and a cosmological constant. Furthermore, we

Figure 1. Neutrino mass eigenvalues as functions of their total for the cases of normal (top panel) and inverted (bottom panel) hierarchies. The vertical line marked ‘oscillations’ is the lower limit derived from the measured mass-squared differences for the two hierarchies. The other vertical lines are upper limits from WMAP+CBI+ACBAR+2dFGRS+Ly α , 2dFGRS, and $^3\text{H } \beta$ decay.

restrict ourselves to adiabatic, linear perturbations. The basic physics is then fairly simple. A perturbation mode of a given wavelength λ can grow if it is greater than the Jeans wavelength λ_J determined by the balance of gravitation and pressure, or rms velocity in the case of massless particles. Above the Jeans scale, perturbations grow at the same rate independently of the scale. Long after matter-radiation equality, all interesting scales are above λ_J and grow at the same rate, and in models where all the dark matter is cold, the time and scale dependence of the power spectrum can therefore be separated at low redshifts. Light, massive neutrinos can, however, move unhindered out regions below a certain limiting length scale, and will therefore tend to damp a density perturbation at a rate which depends on their rms velocity. The

presence of massive neutrinos therefore introduces a new length scale, given by the size of the co-moving Jeans length when the neutrinos became non-relativistic. In terms of the comoving wavenumber, this is given by

$$k_{\text{nr}} = 0.015 \left(\frac{m_{\nu, \text{tot}}}{1 \text{ eV}} \right)^{1/2} \Omega_{\text{m}}^{1/2} h \text{ Mpc}^{-1}, \quad (3)$$

for three equal-mass neutrinos. The growth of Fourier modes with $k > k_{\text{nr}}$ will be suppressed because of neutrino free-streaming. The free-streaming scale varies with the cosmological epoch, and the scale and time dependence of the power spectrum cannot be separated, in contrast to the situation for models with cold dark matter only.

The transfer functions of the perturbations in the various components provide a convenient way of describing their evolution on different scales. Using the redshift z to measure time, the transfer function is formally defined as

$$T(k, z) = \frac{\delta(k, z)}{\delta(k, z = z_*) D(z_*)} \quad (4)$$

where $\delta(k, z)$ is the density perturbation with wavenumber k at redshift z , and D is the linear growth factor. The normalization redshift z_* corresponds to a time long before the scales of interest have entered the horizon. The transfer function thus gives the amplitude of a given mode k at redshift z relative to its initial value, and is normalized so that $T(k = 0, z) = 1$. The power spectrum of the matter fluctuations can be written as

$$P_{\text{m}}(k, z) = P_*(k) T^2(k, z), \quad (5)$$

where $P_*(k)$ is the primordial spectrum of matter fluctuations, commonly assumed to be a simple power law $P_*(k) = Ak^n$, where A is the amplitude and the spectral index n is close to 1. It is also common to define power spectra for each component, see [32] for a discussion. Note that the transfer functions and power spectra are independent of the value of the cosmological constant as long as it does not shift the epoch of matter-radiation equality significantly.

Accurate determination of the transfer function requires the solution of the coupled fluid and Boltzmann equations for the various components. This can be done using one of the publicly available codes, e.g. CMBFAST [33] or CAMB [34]. Analytical approximations are also available, and they are very useful when one wants very quick computation of transfer functions. Accurate fitting formulas for the transfer function were derived by [32]. These analytic approximations are good at realistic baryon fractions, i.e. 0.1-0.2, with the errors typically smaller than 4 %. In figure 2 we show the transfer functions for models with $\Omega_{\text{m}} = 0.3$, $\Omega_{\text{b}} = 0.04$, $h = 0.7$ held constant, but with varying neutrino fraction. One can clearly see that the small-scale suppression of power becomes more pronounced as the neutrino fraction $f_{\nu} \equiv \Omega_{\nu}/\Omega_{\text{m}}$ increases. The suppression of the power spectrum on small scales is roughly proportional to f_{ν} :

$$\frac{\Delta P_{\text{m}}(k)}{P_{\text{m}}(k)} \sim -8f_{\nu}. \quad (6)$$

Figure 2. Ratio of the transfer functions for various values of Ω_ν to the one for $\Omega_\nu = 0$. The other parameters are fixed at $\Omega_m = 0.3$, $\Omega_b = 0.04$, $h = 0.7$.

3. Constraining the total neutrino mass with the 2dFGRS

In an earlier short paper [12] we used the power spectrum of the galaxies as measured by the 2dFGRS to limit the fractional contribution $f_\nu = \Omega_\nu / \Omega_m$ to the matter density of massive neutrinos, and on their total mass $m_{\nu, \text{tot}} = 94 \Omega_\nu h^2$ eV. The present section starts with a short summary of the 2dFGRS and the analysis in [12] before going into a more detailed discussion of the various ingredients involved in the analysis. In [1] the WMAP team derived a stronger limit on the total neutrino mass than what was obtained from the 2dFGRS + various priors. However, the 2dFGRS power spectrum played a central role in the WMAP neutrino mass limit. As the CMB is insensitive to neutrino masses in the eV range, the main role of the WMAP data is to provide tight constraints on parameters that may otherwise partly mimic the effect of massive neutrinos on the matter power spectrum. Therefore our discussion of priors should also be of interest in understanding how the WMAP limit was obtained.

3.1. The 2dF Galaxy Redshift Survey

The 2dF Galaxy Redshift Survey [35] has measured the redshifts of more than 230 000 galaxies with a median redshift of $z_m \approx 0.11$. One of the main goals of the survey was to measure the galaxy power spectrum on scales up to a few hundred Mpc, thus filling in the gap between the small scales covered by earlier galaxy surveys and the largest scales where the power spectrum is constrained by observations of the CMB. A sample of the size of the 2dFGRS survey allows large-scale structure statistics to be measured with very small random errors. An initial estimate of the convolved, redshift-space power spectrum of the 2dFGRS has been determined [36] based on a sample of 140 000 redshifts. On scales $0.02 < k < 0.15 h \text{ Mpc}^{-1}$ the data are robust and the shape

Figure 3. Ratio of power spectra for $\Omega_\nu = 0.01$ (bottom line) and $\Omega_\nu = 0.05$ (top line) to the one for $\Omega_\nu = 0$ (horizontal line) with amplitudes fitted to the 2dFGRS power spectrum data (vertical bars) in redshift space. We have fixed $\Omega_m = 0.3$, $h = 0.7$, and $\Omega_b h^2 = 0.02$. The vertical dashed lines limit the range in k used in the fits.

of the power spectrum is not affected by redshift-space or nonlinear effects, though the amplitude is increased by redshift-space distortions. One should bear in mind that what is measured is the convolution of the true galaxy power spectrum with the window function of the survey [36, 37],

$$P_{\text{conv}}(\mathbf{k}) \propto \int P_g(\mathbf{k} - \mathbf{q}) |W_k(\mathbf{q})|^2 d^3q, \quad (7)$$

where W is the window function.

As an illustration of the potential of the 2dFGRS to constrain neutrino masses, we show in figure 3 the ratio of the power spectra for $\Omega_\nu = 0.01$, and 0.05 (all other parameters are fixed at their ‘concordance model’ values given in the figure caption) to the power spectrum for $\Omega_\nu = 0$ after they have been convolved with the survey window function, and their amplitudes fitted to the 2dFGRS power spectrum data. It is seen from figure 3 that the error bars on the power spectrum data points are correlated, as discussed in [36], and this is taken into account throughout this paper by using the full covariance matrix of the data when computing likelihoods. For the 32 data points, the $\Omega_\nu = 0$ -model had $\chi^2 = 32.9$, $\Omega_\nu = 0.01$ gives $\chi^2 = 33.4$, whereas the model with $\Omega_\nu = 0.05$ provides a poor fit to the data with $\chi^2 = 92.2$.

3.2. Previous results from the 2dFGRS

In [12] six parameters were used to describe the matter power spectrum:

- The fraction of massive neutrinos (hot dark matter) $f_\nu \equiv \Omega_\nu / \Omega_m$.
- The combination $\Omega_m h$, which describes the shape of the cold dark matter power spectrum.

- The baryon fraction $f_b \equiv \Omega_b/\Omega_m$.
- The present value of the Hubble parameter h .
- The scalar spectral index of the primordial density perturbation spectrum, n .
- The amplitude A of the galaxy power spectrum.

The amplitude is a free parameter to take into account the fact that what is measured is the power spectrum of galaxies, not of all the matter, and that it is measured in redshift space, not in real space. The latter effect has been shown in [36] to correspond to a shift in the amplitude of the spectrum. The first effect is parametrized by the so-called bias parameter

$$b^2(k) = \frac{P_g(k)}{P_m(k)}. \quad (8)$$

The scale-dependence of the bias factor is not well known. We will discuss this in more detail in a later subsection, for the time being we note that one would expect the relation between the distribution of dark matter and luminous matter to be simple on large scales. This is borne out by numerical simulations [38], and two independent analyses have shown that the 2dFGRS power spectrum is consistent with a constant bias on the scales relevant for our analysis [39, 40]. Thus, we took the redshift space distortions and the bias into account by leaving the amplitude A of the power spectrum as a free parameter, which means that we used the *shape* of the 2dFGRS power spectrum, and not its amplitude, to constrain f_ν .

The main effect of the massive neutrinos is to reduce the power on scales smaller than the neutrino free-streaming scale. This effect may, however, be partially masked by other effects. Obviously, lowering the amplitude or the scalar spectral index n will reduce the power. Also, the baryon fraction and $\Omega_m h$ interfere with the neutrino signal. Therefore, constraints on the neutrino mass from the galaxy power spectrum depends on the information we have about other parameters (‘priors’). In [12] we added constraints from independent cosmological probes: a Gaussian prior on the Hubble parameter $h = 0.70 \pm 0.07$, consistent with the results from the HST Hubble Key Project [41], a Gaussian prior $\Omega_b h^2 = 0.020 \pm 0.002$ on the physical baryon density from Big Bang Nucleosynthesis [42], and a Gaussian prior $n = 1.0 \pm 0.1$ on the scalar spectral index. Furthermore, we considered two different priors on Ω_m :

- Under the assumption of $\Omega_m + \Omega_\Lambda = 1$, a Gaussian prior $\Omega_m = 0.28 \pm 0.14$ was obtained from surveys of high redshift Type Ia supernovae [43, 44].
- A uniform (‘top hat’) prior in the range $0.1 < \Omega_m < 0.5$. Given our prior on h , $\Omega_m < 0.5$ ensured that the ages of the Universes in the models considered were greater than 12 Gyr.

As noted earlier, the transfer function does not depend on Ω_Λ and so the assumption $\Omega_m + \Omega_\Lambda = 1$ enters only through the Supernova Type Ia prior on Ω_m .

For each set of parameters, we computed the theoretical matter power spectrum, and obtained the χ^2 for the model given the 2dFGRS power spectrum. We then

Figure 4. Probability distributions, normalized so that the area under each curve is equal to one, for f_ν with marginalization over the other parameters, as explained in the text, for $N_\nu = 3$ massive neutrinos and $\Omega_m h = 0.16$ (full line), 0.20 (dotted line), and 0.24 (dashed line).

calculated the joint probability distribution function for f_ν and $\Gamma \equiv \Omega_m h$ (which represents the shape of the CDM power spectrum) by marginalizing over A, h and f_b weighted by the priors given above. For A we used a uniform prior in the interval $0.5 < A < 10$, where $A = 1$ corresponds to the normalization of the ‘concordance model’, discussed in [39]. Using instead a prior uniform in $\log A$, or fixing A at the best-fit value had virtually no effect on the results. Figure 4 shows the probability distributions for f_ν for three different values of $\Omega_m h$. Marginalizing over $\Omega_m h$ using the uniform prior on Ω_m , we got an upper limit $f_\nu < 0.13$ at 95% confidence for $n = 1$. Increasing n increases power on small scales and leaves more room for suppression by the massive neutrinos, and upon marginalizing over the full range of n with a prior $n = 1.0 \pm 0.1$ we found $f_\nu < 0.16$ at 95 % confidence. For $\Omega_m h^2 = 0.15$ this corresponds to a total neutrino mass $m_{\nu, \text{tot}} = 2.2$ eV. The results with the Supernova Type Ia prior on Ω_m were identical. For comparison, marginalizing without any priors, the limit becomes $f_\nu < 0.24$. Adding just a prior on Ω_m , we find $f_\nu < 0.15$, so this is clearly the most important prior. Marginalizing with just a prior on h or on $\Omega_b h^2$, the 95 % confidence limit becomes $f_\nu < 0.20$. Clearly the priors play a crucial role in the analysis, and we will discuss their role in the next subsections. To facilitate the comparison with the WMAP analysis in [1] we will from now on carry out our analysis in terms of the physical densities $\omega_i = \Omega_i h^2$, where $i = m, \nu, b$.

3.3. The prior on ω_m

As noted above, the prior on the matter density is crucial, and the tight correlation between $m_{\nu, \text{tot}}$ and ω_m is illustrated in figure 5. In fact, without a prior on ω_m no non-

Figure 5. Confidence contours (68 and 95 %) from the 2dFGRS data alone in the plane of total neutrino mass $m_{\nu, \text{tot}} = 94\omega_\nu$ eV and the physical matter density ω_m . The bias parameter and σ_8 have been marginalized over with top-hat priors, ω_b , h , and n are fixed at their best-fitting values.

trivial upper limit on ω_ν is obtained (but note that one still finds an upper limit on f_ν). WMAP provides a constraint $\omega_m = 0.14 \pm 0.02$ for spatially flat Λ CDM models, but it is interesting to note that one from the CMB and 2dFGRS alone cannot rule out models with $\Omega_m = \Omega_{\text{CDM}} + \Omega_b + \Omega_\nu = 1$. To illustrate this point, we consider the following three models, all with $\omega_b = 0.024$:

- (i) A Mixed Dark Matter (MDM) model with $\Omega_m = 1$, $\Omega_\nu = 0.2$, $h = 0.45$, and $n = 0.95$. The neutrino mass fraction is thus $f_\nu = 0.2$.
- (ii) A Λ CDM model with $\Omega_m = 0.3$, $\Omega_\nu = 0$, $h = 0.7$, and $n = 1.0$.
- (iii) A pure CDM model with $\Omega_m = 1$, $\Omega_\nu = 0$, $h = 0.45$, and $n = 0.95$.

For the pre-WMAP CMB, we use the recent compilation in [45]. Model 1 has $\chi^2/\text{datum} = 1.14$ for the CMB (28 points) and $\chi^2/\text{datum} = 1.13$ for the 32 2dFGRS power spectrum data points. Model 2 has $\chi^2/\text{datum} = 1.11$ for the CMB, $\chi^2 = 1.03$ for the 2dFGRS. The WMAP data discriminate better between these two models, Model 1 having $\chi^2/\text{datum} = 1.15$ (899 points) and model 2 $\chi^2/\text{datum} = 1.08$, but we see from figure 6 that the models are look reasonable and note that we have not carried out any systematic search for a best-fitting model of the three types. Thus, the first two models seem to offer acceptable descriptions of the CMB and 2dFGRS data, and from these data alone MDM is still a viable alternative to the ‘concordance’ Λ CDM. So why did several pre-WMAP studies find that the CMB and 2dFGRS prefer a low matter density and a cosmological constant? This is because they considered (very reasonably) neutrinos to be essentially massless. Model 3 illustrates the point: it is a pure CDM model with massless neutrinos. It gives a reasonable description of the CMB data, but has $\chi^2 = 67$ for the 2dFGRS data points, and hence it will be disfavoured in a joint analysis. The CMB cannot distinguish between eV-mass neutrinos and cold dark matter, and hence model 1 and 3 provide comparable descriptions of the CMB data,

but the galaxy power spectrum does distinguish between the two, and massive neutrinos provides the necessary reduction in small-scale power to fit the data points. Of course, one cannot look at the CMB and 2dFGRS data alone, and it is not our intention to ‘resurrect’ the MDM model: it has problems with the evolution of cluster abundances with redshift [46], needs a low value of the Hubble parameter, and $\Omega_m = 1$ is clearly at variance with independent measurements from e.g. the baryon fraction in clusters [47], but we wish to make the two following points:

- The CMB + 2dFGRS alone cannot rule out MDM; one needs a further prior, e.g. the Hubble constant from HST [41], supernovae Type Ia [43, 44], a prior on Ω_m from the cluster baryon fraction [47], or evolution of cluster abundance with redshift [46].
- The statement that CMB + 2dFGRS alone provides evidence independent of that of supernovae Type Ia for a cosmological constant/dark energy is too strong. This result is obtained only when neutrino masses are assumed to be negligible. If one allows for massive neutrinos, acceptable fits to the CMB+2dFGRS can be obtained with $\Omega_m = 1$ and $\Omega_\nu \sim 0.2$.

3.4. The prior on the Hubble parameter

We saw in the previous subsection that if we low values of the Hubble constant, $h < 0.5$, MDM models provide reasonable fits to the CMB and 2dFGRS power spectra, but by combining with the HST prior on h , one will obtain the by now usual ‘concordance’ values $\Omega_m \sim 0.3$, $\Omega_\Lambda \sim 0.7$. The derivation of a strong upper limit on the total neutrino mass therefore depends on our ability to exclude values of h much below 0.7. Figure 7 shows the degeneracy between h and ω_ν . If we allow $\Omega_m = 1$, and drop the prior on h , we find that a universe with a low value of $h < 0.5$ is a viable option if the total neutrino mass is a few eVs. Note that these models also have ages > 12 Gyr, consistent with ages of globular clusters [48]. Thus, without a prior on h , the CMB prior on Ω_m would have been weaker, and which would also have affected the upper limit on the neutrino masses.

3.5. The prior on the scalar spectral index

As noted earlier, there is also a degeneracy between the scalar spectral index n and ω_ν , illustrated in figure 8. Motivated by the pre-WMAP CMB data we used a prior $n = 1.0 \pm 0.1$ in [12]. For flat Λ CDM models the WMAP data give $n = 0.99 \pm 0.04$ (see table 1 in [1]), but in their full analysis including other datasets there is some evidence for a running scalar spectral index. However, it has been argued that this may be because of their treatment of the Lyman α forest power spectrum, and that in a more conservative approach one finds that a scale-invariant primordial power spectrum, $n = 1$ is consistent with the data [49]. We will therefore not consider a running spectral index in this paper.

Figure 6. MDM ($\Omega_m = 1$, $\Omega_\nu = 0.2$, $h = 0.45$, $n = 0.95$), CDM ($\Omega_m = 1$, $\Omega_\nu = 0$, $h = 0.45$, $n = 0.95$) and Λ CDM ($\Omega_m = 1$, $\Omega_\Lambda = 0.7$, $\Omega_\nu = 0$, $h = 0.7$, $n = 1.0$) models (all with $\Omega_b h^2 = 0.024$) compared with data. The upper panel shows the pre-WMAP data, the middle panel the WMAP data and the lower panel the 2dFGRS data along with the three models considered. We have normalized the models to each data set separately, but otherwise these are assumed models, not formal best fits.

Figure 7. Confidence contours (68 and 95 %) from the 2dFGRS data alone in the $m_{\nu, \text{tot}} - h$ plane. The bias parameter and σ_8 have been marginalized over with top-hat priors, while ω_m , ω_b , and n have been fixed at their best-fitting values.

Figure 8. Confidence contours (68 and 95 %) from the 2dFGRS data alone in the $m_{\nu, \text{tot}} - n$ plane. The bias parameter and σ_8 have been marginalized over with top-hat priors, while ω_m , ω_b and h have been fixed at their best-fitting values.

3.6. The prior on the baryon density

There is also some degeneracy between the baryon density and the neutrino masses, as shown in figure 9, because increasing the baryon density suppresses power on small scales. The degeneracy is, however, less serious than for the other parameters, and WMAP provides a tight constraint on ω_b from the ratio of the amplitudes of the first and second peaks in the CMB power spectrum, $\omega_b = 0.024 \pm 0.001$, consistent with standard BBN [42].

Figure 9. Confidence contours (68 and 95 %) from the 2dFGRS data alone in the $m_{\nu, \text{tot}} - \omega_b$ plane. The bias parameter and σ_8 have been marginalized over with top-hat priors, while ω_m , h , and n have been fixed at their best-fitting values.

3.7. Non-linear fluctuations

At small scales, one eventually enters the regime where the power spectrum is no longer linear. Therefore, as a further test of the stability of our analysis in [12], we used the full set of priors, but only the power spectrum data at scales $k < 0.1 \, h \, \text{Mpc}^{-1}$ and found that the limit increased to $f_\nu < 0.20$. Cutting the power spectrum at this scale is, however, very conservative. To see this, we follow the analysis of non-linearities in [50]. Defining

$$\Delta^2(k) \equiv \frac{k^2}{2\pi^2} P(k), \quad (9)$$

the crossover from linear to non-linear behaviour is at the co-moving momentum k_{cut} where $\Delta^2(k_{\text{cut}}) = 1$. This corresponds roughly to the point where $\Delta_{\text{non-linear}}^2 - \Delta_{\text{linear}}^2 \sim \Delta_{\text{linear}}^2$. We use the approximate relation between the linear and non-linear spectrum found by [51]. The cut in the spectrum should be made where the non-linear effects are of the same order as the suppression of small scale-power from massive neutrinos, which is given by equation (6). For neutrino masses $\sim 1 \, \text{eV}$, this gives $\Delta_{\text{linear}}^2 \sim 3$. We chose $k_{\text{cut}} = 0.15 \, h \, \text{Mpc}^{-1}$ in our analysis, and at that point $\Delta_{\text{linear}}^2 \approx 0.7$. Crude as this argument may be, it clearly indicates that the neutrino mass signal dominates possible non-linear effects in the 2dFGRS power spectrum data used in our analysis. We note that the linear matter power spectrum is convolved with the survey window function before comparison with the data. However, for values of k greater than $\sim 0.1 \, h \, \text{Mpc}^{-1}$ the window function is sharply peaked at k , and so there is little mixing with smaller scales [37]. The WMAP team went one step further and considered non-linear corrections at the smallest scales in the analysis. Nevertheless, one would expect these effects to be small for $k < 0.15 \, h \, \text{Mpc}^{-1}$.

3.8. Scale-dependent bias

The power spectrum of the galaxy distribution might be ‘biased’ relative to the matter power spectrum, hence it might introduce systematic error in the estimation of the neutrino mass.

Indeed it is well established that on scales less than ~ 10 Mpc different galaxy populations exhibit different clustering amplitudes, the so-called morphology-density relation (e.g. [52, 53, 54, 55]). Hierarchical merging scenarios also suggest a more complicated picture of biasing as it could be non-linear, scale-dependent and stochastic (e.g. [38, 56, 57, 58, 59, 60, 61]). But is the biasing still scale-dependent at the large scales ($k^{-1} > 7 h^{-1}$ Mpc) where we analyse the 2dFGRS power spectrum? Let us consider the ratio of galaxy to matter power spectra, and use the ratio of these to define the bias parameter as in equation (8). To illustrate the dramatic effect that scale-dependent might have we assume the following simple form:

$$b(k) = a \log(k/k^*) + c, \quad (10)$$

where we fix $k^* = 0.15 h \text{ Mpc}^{-1}$ (note that a shift in k^* can be absorbed in a change in c), but allow a and c to vary.

Analysis of the semi-analytic galaxy formation models in [62] shows that on large scales the biasing function $b(k)$ is nearly constant to high degree. In our parameterization (10) even the brightest galaxies ($L > 0.75 L_*$, where L_* is the characteristic luminosity of the Schechter luminosity function) are weakly biased, with slope $a < 0.15$ over the scales $3 < k^{-1} < 16 h^{-1} \text{ Mpc}$ [63]. The simulations in [60] also suggest scale-independent biasing on scales larger than $10 h^{-1} \text{ Mpc}$ at late times.

Observationally, the bi-spectrum analysis of the 2dFGRS showed almost no deviation from linear biasing [40] and combined analysis of 2dFGRS with CMB data on scales of $0.02 < k < 0.15 h \text{ Mpc}^{-1}$ [39] gave $b \sim 1$ for L_* galaxies. Furthermore, the ratio of the power-spectra of blue and red galaxies in 2dFGRS [64] is almost constant over the range of our analysis, $0.02 < k < 0.15 h \text{ Mpc}^{-1}$. This suggests (as a necessary, but not sufficient condition) that the galaxy power spectrum is proportional to the underlying matter power spectrum. Based on these theoretical and observational studies we argue that scale-dependent biasing is unlikely to pose a problem in estimating the neutrino mass from the 2dFGRS.

We then redo the analysis of the 2dFGRS $P_g(k)$ with ω_ν , a and c as free parameters. The remaining parameters are fixed at their ‘concordance’ values ($\Omega_m = 0.3$, $h = 0.7$ etc.). We distinguish between two cases: $a \leq 0$ (bias increasing with length-scale) and $a \geq 0$ (bias decreasing with length-scale). In the first case, the best fit is found at $\omega_\nu = 0$, $a = 0$, whereas in the second case one finds the best fit for $\omega_\nu \approx 0.029$, $a = 0.72$, $c = 1.1$, i.e. for a non-zero neutrino mass $m_{\nu, \text{tot}} \approx 2.8 \text{ eV}$. This is understandable, since $b(k)$ in this case has the opposite effect of massive neutrinos, so the two effects can be ‘tuned’ to give a very good fit to the 2dFGRS data with a non-zero neutrino mass which is unrealistically high. Figure 10 shows the likelihood contours in the $m_{\nu, \text{tot}}-a$ plane. As

Figure 10. Likelihood contours (68, 95, and 99 %) in the $m_{\nu, \text{tot}}-a$ plane after marginalizing over c , where a and c are defined in equation (10). The horizontal line $a = 0.15$ is an upper limit estimated from simulations of biasing (see text).

argued above, simulations and observations argue for $a < 0.15$ at large scales, and in what follows we shall assume constant biasing.

3.9. The case of scale-independent bias in more detail

WMAP provides tight constraints on ω_m , h , n , and ω_b , and we have seen in previous subsections that having good constraints on these parameters is essential to obtaining a good upper limit on $m_{\nu, \text{tot}}$. Also, from the CMB one can constrain the amplitude of the matter power spectrum (quoted, e.g. in terms of the rms mass fluctuations in spheres of radius $8 h^{-1}$ Mpc, σ_8). If the biasing and redshift-space distortions were known, then this would translate directly to a constraint on the amplitude of the 2dFGRS power spectrum, and could potentially tighten the constraint on $m_{\nu, \text{tot}}$. The WMAP analysis makes use of the constraint on the amplitude of the matter power spectrum from the CMB by introducing a prior on the bias parameter, taking it to be a Gaussian with $b = 1.04 \pm 0.11$ [65] as found in the analysis of the 2dFGRS bispectrum [40]. As the analysis in [40] was performed for a different range of scales than those involved in the analysis of the linear part of the 2dFGRS power spectrum, and did not take neutrino masses into account (even though the cosmology dependence in the bispectrum analysis is mild) and questions have been raised about this approach [66], it is worthwhile to take a closer look at the WMAP approach. To do this, we need to go into the issue of a constant bias and redshift-space distortions in more detail than in the previous sections, and we will do so following [39]. The WMAP analysis was more detailed [65], but we think that our simplified version captures the main points.

We now need to take two effects into account: the fact that the 2dFGRS power spectrum is given in redshift space, and that the galaxy distribution may be biased with respect to the mass distribution. At redshift $z = 0$, the relation between the real-space normalization at redshift 0, $\sigma_{8m}(0)$, of the matter power spectrum and the normalization

of the galaxy power spectrum is given by

$$\sigma_{8g}^R(L_s, 0) = b(L_s, 0)\sigma_{8m}(0), \quad (11)$$

where $L_s \approx 1.9L_*$ for the 2dFGRS. We follow [39] and assume that galaxy clustering evolves weakly in the range of redshifts $0 < z < 0.2$ so that $\sigma_{8g}^R(L_s, z_s) \approx \sigma_{8g}^R(L_s, 0)$, where $z_s \approx 0.17$. The conversion of σ_{8g} from real space to redshift space is determined by

$$\sigma_{8g}^S(L_s, z_s) = \sigma_{8g}^R(L_s, z_s)\sqrt{K[\beta(L_s, z_s)]}, \quad (12)$$

where

$$K[\beta] = 1 + \frac{2}{3}\beta + \frac{1}{5}\beta^2, \quad (13)$$

is Kaiser's factor [67], and

$$\beta(L_s, z_s) \approx \frac{\Omega_m^{0.6}(z_s)}{b(L_s, z_s)}, \quad (14)$$

with

$$\Omega_m(z) = \frac{\Omega_m(1+z)^3}{\Omega_m(1+z)^3 + \Omega_\Lambda}. \quad (15)$$

Furthermore, we assume that the mass fluctuations grow as $\sigma_{8m}(z) = \sigma_{8m}(0)D(z)$, where $D(z)$ is the linear growth rate (normalized to 1 at $z = 0$). As pointed out earlier, the linear growth rate is actually scale dependent in models with massive neutrinos. We have checked that this scale dependence is weak for the parameter range we consider, and evaluated $D(z)$ at $k = \bar{k}$, where $\bar{k}$ is the mean value of k for a spherical top-hat window function. With these assumptions we have

$$b(L_s, z_s) = \frac{b(L_s, 0)}{D(z_s)}. \quad (16)$$

Given $b(L_s, 0)$, we can translate a given normalization $\sigma_{8m}(0)$ of the matter power spectrum to $\sigma_{8g}^S(L_s, z_s)$ for the galaxy power spectrum.

We now carry out the following simple analysis: we fix $n = 0.99$, $\Omega_b h^2 = 0.024$ (all values taken from table 1 in [1] for WMAP alone), and fit ω_ν , ω_m , h , σ_{8m} and $b(L_s, 0)$ to the combination of the 2dFGRS power spectrum data and the constraint $\sigma_{8m}\Omega_m^{0.6} = 0.44 \pm 0.10$ from table 2 in [1]. Furthermore, we add Gaussian priors $\Omega_m h^2 = 0.14 \pm 0.02$, $h = 0.72 \pm 0.05$ from WMAP, and look at the limit on $m_{\nu, \text{tot}} = 94\Omega_\nu h^2$ eV for the cases of with and without a prior on $b \equiv b(L_s, 0)$. The results reveal that the prior on ω_m is crucial and the prior on h very important, but also that, at least in this simplified analysis, the effect of adding a prior on the bias is very small, as can be seen from figure 11. Without a prior on ω_m , no non-trivial limit on $m_{\nu, \text{tot}}$ is obtained. With just the ω_m prior, the 95 % confidence limit is $m_{\nu, \text{tot}} < 1.6$ eV, and this improves to 1.1 eV when the prior on h is added. Adding the prior on b does not change the limit on $m_{\nu, \text{tot}}$, it stays at 1.1 eV. From the contour plots in figure 12, the degeneracy between ω_ν and b is small, especially when the prior on ω_m is included. This is not in contradiction to the analysis in [23], because our treatment of

Figure 11. Probability distributions for the total neutrino mass in our simplified analysis after marginalizing over ω_m , h , and b for the cases of a prior on ω_m only, and priors on ω_m and h . When a Gaussian prior $b = 1.04 \pm 0.11$ is added, the resulting curve is indistinguishable from the dashed line.

Figure 12. Confidence contours (68 and 95 plane after marginalizing over ω_m and h for the cases of a prior on ω_m , and priors on both ω_m and h .

biasing is different: we have treated the redshift-space distortions explicitly, and then the constraint on σ_8 and ω_m from the CMB breaks much of the degeneracy between ω_ν and b . This is because the redshift distortion itself depends on Ω_m , see equations (13,14).

In this simple analysis we get a 95 % confidence limit of $m_{\nu, tot} < 1.1$ eV. This is still some way from the WMAP limit of 0.71 eV, even with our very restricted parameter space, but consistent with the analysis in [23]. The WMAP analysis also used data from ACBAR and CBI [14, 15], and included the Lyman α forest power spectrum. The linear matter power spectrum inferred from the Lyman α forest probes smaller scales than the

2dFGRS and therefore has considerable power in constraining neutrino masses. We have seen that the most severe degeneracies of ω_ν are with ω_m , n , h , and ω_b . The most serious one is with ω_m : without a prior on the physical matter density, one cannot get a non-trivial upper bound on $m_{\nu,\text{tot}}$. This makes sense, as the matter power spectrum depends on $f_\nu = \Omega_\nu/\Omega_m$ and this is why the analysis was carried out in terms of this parameter in [12]. So the fact that WMAP (restricted to flat Λ CDM models and $h > 0.5$) provides a tight constraint $\omega_m = 0.14 \pm 0.02$ is crucial for constraining neutrino masses. WMAP also constrains the spectral index to a narrow interval around $n = 1$, and, just as importantly, by constraining h to be around 0.7 eliminates the possibility for MDM models with large neutrino masses to give good fits to the 2dFGRS power spectrum. The importance of the prior on h was also noted in [23].

4. Other cosmological probes of neutrino masses

Direct probes of the total matter distribution avoid the issue of biasing and are therefore ideally suited for providing limits on the neutrino masses. Several ideas for how this can be done exist. In [68] the normalization of the matter power spectrum on large scales derived from COBE was combined with constraints on σ_8 from cluster abundances and a constraint $m_{\nu,\text{tot}} < 2.7$ eV obtained, although with a fairly restricted parameter space. However, σ_8 is probably one of the most debated numbers in cosmology at the moment [45], and a better understanding of systematic uncertainties connected with the various methods for extracting it from observations is needed before this method can provide useful constraints. The potential of this method to push the value of the mass limit down also depends on the actual value of σ_8 : the higher σ_8 turns out to be, the less room there will be for massive neutrinos. The evolution of cluster abundance with redshift may provide further constraints on neutrino masses [46]. The Lyman α forest provides constraints on the matter power spectrum on small scales, where the effect of massive neutrinos is most visible, and it was used in [69] to derive a limit $m_{\nu,\text{tot}} < 5.5$ eV, and it clearly played a role in the WMAP limit also. How to use this probe correctly in cosmological parameter estimation is, however, still being discussed [49]. Massive neutrinos also suppress peculiar velocities on scales smaller than $50 h^{-1}$ Mpc, where they can be measured more accurately to nearby galaxies, however, non-linear effects on small scales causes complications. Finally, deep and wide weak lensing surveys will in the future make it possible to do weak lensing tomography of the matter density field [70, 71], and in [72] it has been shown that one can probe neutrino masses below 0.1 eV in this way. However, this is under the assumption that the equation of state of the dark energy is known.

5. Conclusions

We have reviewed how the constraint on the neutrino mass in [12] was obtained, and the recent improved limit from WMAP, paying attention to issues of priors and parameter

degeneracies. We have seen that one can derive fairly tight constraints on neutrino masses from the 2dFGRS power spectrum, provided that one has good constraints on ω_m , n , h , and ω_b from independent data sets.

We found that external constraints on the Hubble parameter, for example the HST Key project, is important in order to get a strong limit on the neutrino mass since, intriguingly, the out-of-fashion Mixed Dark Matter (MDM) model can give a reasonable description of the CMB and 2dFGRS data with $\Omega_\nu = 0.2$, $\Omega_m = 1$ and no cosmological constant if we allow low values of the Hubble parameter, $h < 0.5$. The importance of having a prior on h was also noted in [23]. We note that the above MDM model is inconsistent with other cosmic measurements such as Supernovae Type Ia, baryon fraction in clusters, and the evolution of cluster abundance with redshift, so adding any one of these datasets to the analysis would eliminate MDM and improve the neutrino mass limit.

We also considered the effect of the possible bias of the galaxy distribution with respect to the mass distribution on the neutrino mass limit. A scale-dependent bias has serious implications for the $m_{\nu,\text{tot}}$ constraint, but based on semi-analytic galaxy formation models [62] the scale-dependence of the bias is expected to be too weak to be of any major concern on the large scales used in the analysis of the 2dFGRS power spectrum. When the effects of redshift-space distortions on the 2dFGRS power spectrum are included in the analysis, there is almost no degeneracy between a constant, scale-independent bias factor and the neutrino mass. However, in our restricted analysis we did not get as good a neutrino mass constraint with 2dFGRS + WMAP priors as in the full analysis in [1] which suggests that the Lyman α forest power spectrum plays a role in pushing the constraint on $m_{\nu,\text{tot}}$ below 1 eV.

Acknowledgments

We thank the 2dFGRS team, and in particular John Peacock for drawing our attention to the MDM issue and for useful comments. We acknowledge fruitful discussions with the Leverhulme Quantitative Cosmology Group in Cambridge. We also thank Andreas Berlind, David Weinberg, and Steen Hannestad for very helpful comments. ØE and OL wish to thank, respectively, the IoA in Cambridge and NORDITA for their hospitality.
